

Supplementary Notes

1. Supplementary Note 1: Distance metric for clustering algorithm

Assume there are 2 Poisson distributions P_1 and P_2 with density functions

$$p_1(x, \lambda_1) = \frac{e^{-\lambda_1} \lambda_1^x}{\Gamma(x+1)}$$

and

$$p_2(x, \lambda_2) = \frac{e^{-\lambda_2} \lambda_2^x}{\Gamma(x+1)}$$

The Kullback-Leibner divergence from P_2 to P_1 is defined as:

$$D_{KL}(P_1||P_2) = \int_{-\infty}^{\infty} p_1(x) \log \frac{p_1(x)}{p_2(x)} dx$$

or in other words, it is the expectation of the logarithmic difference between the probabilities P_1 and P_2 , where the expectation is taken with regard to P_1 .

The log ratio of the density functions is

$$\log \frac{p_1(x)}{p_2(x)} = x \log \frac{\lambda_1}{\lambda_2} + \lambda_2 - \lambda_1$$

take expectation of this expression with regard to P_1 with mean λ_1 we have

$$D_{KL}(P_1||P_2) = \lambda_1 \log \frac{\lambda_1}{\lambda_2} + \lambda_2 - \lambda_1$$

The metric we used is the distance defined as

$$D(P_1, P_2) = \frac{D_{KL}(P_1||P_2) + D_{KL}(P_2||P_1)}{2} = \frac{1}{2}(\lambda_1 - \lambda_2)(\log \lambda_1 - \log \lambda_2)$$

2. Supplementary Note 2: Coverage re-estimation

The re-estimation is basically carried out by following two steps.

1. From nodes coverage, estimate edges' value by quadratic unconstrained optimization of the least-square function:

$$\frac{1}{2} \sum_i l_i ((\sum e_i^+ - c_i)^2 + (\sum e_i^- - c_i)^2)$$

where l_i and c_i is the length and coverage of a node i in the graph;

$\sum e_i^+$ and $\sum e_i^-$ indicates sum of the values of incoming and outgoing edges from i respectively. The above function and be rewritten as:

$$f(x) = \frac{1}{2} x^T Q x + b^T x + r$$

and then being minimized by using gradient-based method.

2. Update nodes' coverage based on itself and its neighbor edges' measures.

The calibration is iterative until no further improvements are made or a threshold loop count is reached.

3. Supplementary Note 3: Contigs binning

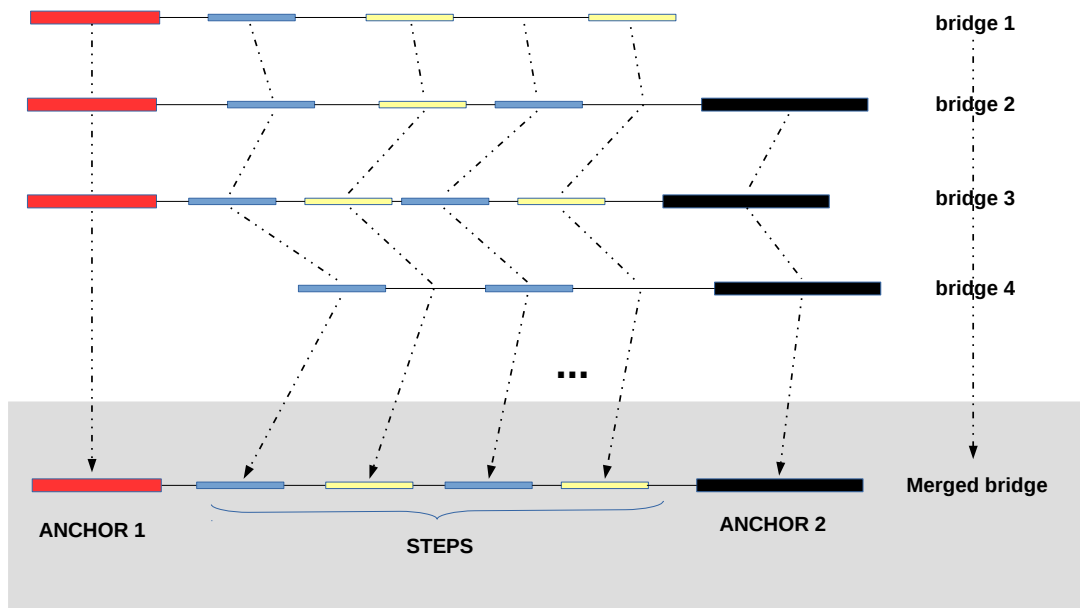

We implemented a simple binning algorithm based on the clustered contigs, the graph topology as well as statistics calculated by length and coverage of each contigs. Additional binning step is taken place in real-time using the long reads as well. In this context, the repetition or uniqueness of ambiguous nodes are determined with sufficient supporting evidence from the long-spanning reads. In general, the algorithm works well for isolate or simple mock metagenomics, but not robust enough for complicated community.

On the other hand, if external binning algorithm is employed, the resulting output must be converted into a text file that specifies the corresponding bin of every contigs, just like output from MetaBAT. By that, each line of the file would be: < contig-ID > < bin-ID > where bin-ID = 0 indicates unspecified binned contigs.

4. Supplementary Note 4: Constructing bridges in real-time

We implemented a data structure to represent the connection between two unique contigs in the assembly graph, namely *bridge*. A bridge has 4 levels of completion, ranging from 1 to 4 depends on how close to finish it is. When a new bridge is built with only one anchor (unique ending), it has level 1. If both anchor nodes are identified, its completion level is 2. Only then, a path finding algorithm is applied to find candidate paths of this bridge. When potential paths (more than 1) are listed successfully, the completion level is increased to 3. Finally, when the only path solution is determined out of all candidates, the bridge is assigned as complete-built with level 4.

At early stages (level 1 or 2), a bridge is constructed progressively by alignments from long reads that spanning its corresponding anchor(s). In an example from Figure 1, bridges from a certain anchor (highlighted in red) are created by extracting appropriate alignments from incoming long reads to the contigs. Each of the steps therefore is assigned a weighing score based on its alignment quality. Due to the error rate of long reads, there should be deviations in terms of steps found and spans measured between these bridges, eventhough they represent the same connection. A continuous merging phase, as shown in the figure, takes advantage of a pairwise Needleman-Wunsch dynamic programming to generate a consensus list based on weight and position of each of every stepping nodes. The spans are calibrated accordingly by averaging out the distances. On the other hand, the score of the merged steps are accumulated over time as well. Whenever a consensus bridge is anchored by 2 unique contigs at both ends and hosting a list of steps with sufficient coverage, it is ready for a path finding in the next step.

Supplementary Figure 1: Bridge merging progressively in real-time. Sequencing long reads induce alignments to the contigs where new bridges are created respectively. Bridges sharing same anchors can be merged together to form the ultimate, more comprehensive bridge (with more step nodes and better approximation of spans between them).

5. Supplementary Note 5: Path finding algorithm

However, due to false alignments from shorter contigs to the long reads, not all of the reported step nodes are necessary to be appeared in the ultimate path resolved by the bridge. In most cases, the accumulated score of each step indicates its likelihood to be the true component of the final solution. For that reason, a strategy similar to binary searching is employed to find a path across 2 anchors of a bridge as shown in Algorithm 2.

Before that, we define Algorithm 1 to demonstrates the path finding algorithm for two nodes given their estimated distance. In which, function `shortestTree(vertex, distance) : (V, Z) → Vn` from line 3 of the algorithm's pseudo code builds a shortest tree rooted from \vec{v} , following its direction until a distance of approximately d (with a tolerance regarding nanopore read error rate) is reached. This task is implemented based on Dijkstra algorithm. This tree is used on line 4 and in function `includedIn()` on line 19 to filter out any node or edge with ending nodes that do not belong to the tree.

Basically, the algorithm keeps track of a stack that contains sets of candidate edges to discover. During the traversal, a variable d is updated as an estimation for the distance to the target. A hit is reported if the target node is reached with a reasonable distance *i.e.* close to zero, within a given tolerance (line 21). A threshold for the traversing depth is set (150) to ignore too complicated and time-consuming path searching.

Note that the `length()` functions for node and edge are totally different. While the former returns the length of the sequence represented by the node, *i.e.* contig from short-read assembly, the latter is usually negative because an edge

Algorithm 1: Pseudo-code for finding paths connecting 2 nodes given their estimated distance.

Data: Assembly graph $G\{V, E\}$

Input: Pair of bidirected nodes \vec{v}_1, \vec{v}_2 and estimated distance d between them

Output: Set of candidate paths connecting \vec{v}_1 to \vec{v}_2 with reasonable distances compared to d

```

1 Function DFS( $\vec{v}_1, \vec{v}_2, d$ ):
2    $P := \text{new List}()$ 
3    $M := \text{shortestTree}(\vec{v}_2, d)$  // build shortest tree from  $\vec{v}_2$  with range  $d$ 
4   if  $M.\text{contain}(\vec{v}_1)$  then
5      $S := \text{new Stack}()$  // stack of sets of edges to traverse
6      $\text{edgesSet} := \text{getEdges}(\vec{v}_1)$  // get all bidirected edges going from  $\vec{v}_1$ 
7      $S.\text{push}(\text{edgesSet})$ 
8      $p := \text{new Path}(\vec{v}_1)$  // init a path that has  $\vec{v}_1$  as root
9     while true do
10       $\text{edgesSet} := S.\text{peek}()$ 
11      if  $\text{edgesSet}.\text{isEmpty}()$  then
12        if  $p.\text{size}() \leq 1$  then
13          break // stop the loop when there is no more edge to discover
14         $S.\text{pop}()$ 
15         $d += p.\text{peekNode}.\text{length}() + p.\text{popEdge}().\text{length}()$ 
16      else
17         $\text{curEdge} := \text{edgesSet}.\text{remove}()$ 
18         $\vec{v} := \text{curEdge}.\text{getOpposite}(p.\text{peekNode}())$ 
19         $S.\text{push}(\text{getEdges}(\vec{v}).\text{includedIn}(M))$ 
20         $p.\text{add}(\text{curEdge})$ 
21        if reach  $\vec{v}_2$  with reasonable  $d$  then
22           $P.\text{add}(p)$ 
23         $d = \vec{v}.\text{length}() + \text{curEdge}.\text{length}()$ 
24   return  $P$ 

```

Algorithm 2: Recursive binary bridging to connect 2 anchor nodes.

Data: Assembly graph $G\{V, E\}$

Input: Bridge $B : \{\vec{v}_0, \dots, \vec{v}_k, \dots, \vec{v}_n\}$ with \vec{v}_0 and \vec{v}_n are two anchors, $\{\vec{v}_k\}, k = 1 \dots (n - 1)$ are steps inbetween

Output: Set of candidate paths connecting \vec{v}_0 to \vec{v}_2 that maximize the likelihood of the step list.

```

1 Function BinaryBridging( $B$ ):
2   /* search for the contig with maximum score from the step list (two ends excluded) */
3    $m := \text{argmax}_k(\vec{v}_k.\text{score}())$ 
4   /* if there is no step inbetween, run path finding algorithm above directly and return the result */
5   if  $M.\text{size}() \equiv 2$  then
6     return DFS( $B.\text{start}(), B.\text{end}().B.\text{distance}()$ )
7   /* divide the original bridge  $B$  into 2 bridges by  $v_m$ :  $BL$  and  $BR$  */
8    $BL := \{B.\text{start}(), \dots, \vec{v}_m\}$ 
9    $BR := \{\vec{v}_m, \dots, B.\text{end}()\}$ 
10  /* Return the join of running recursive function on two sub-bridges */
11  return BinaryBridging( $BL$ )  $\bowtie$  BinaryBridging( $BR$ )

```

models a link between two nodes, which is normally an overlap (except for composite edges). For example, in a k -mers SPAdes assembly graph, the value of an edge is $-k + 1$.

6. Supplementary Note 6: Output the results

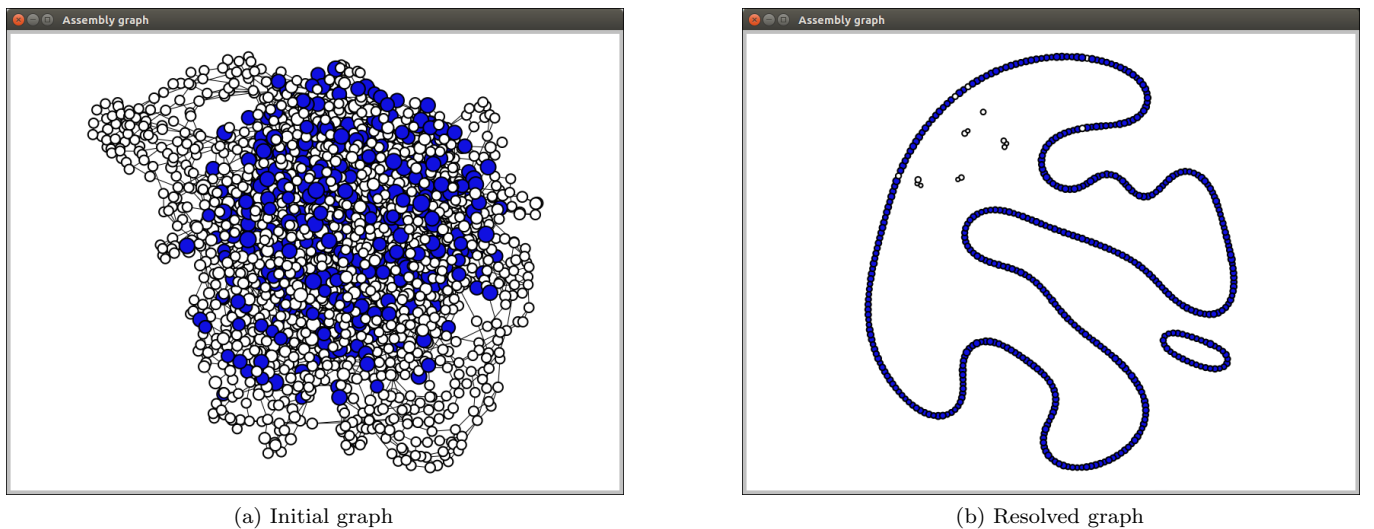

The resolved assembly graph can be reported as a whole (GFA) or sequences only (FASTA).

For the latter, longest-possible linear straight paths must be extracted from the graph for the final FASTA records. A path $p = \{v_0, e_1, v_1, \dots, v_{k-1}, e_k, v_k\}$ of size k is considered as straight if and only if each of every edges along the path $e_i, \forall i = 1, \dots, k$ is the only option to traverse from either v_{i-1} or v_i , giving the transition rule. To decompose the graph, the tool simply mask out all incoming/outgoing edges rooted from any node with in/out degree greater than 1 as demonstrated in Figure 2. These edges are defined as branching edges which stop straight paths from further extending.

Supplementary Figure 2: Example of graph decomposition into longest straight paths. Branching edges are masked out (shaded) leaving only straight paths (bold colored) to report. There would be 3 contigs extracted by traversing along the straight paths here.

The decomposed graph is only used to report the contigs that can be extracted from an assembly graph at certain time point. For that reason, the branching edges are only masked but not removed from the original graph as they would be used for further bridging.

Supplementary Figure 3: Assembly graph of *Shigella dysenteriae* Sd197 synthetic data being resolved by npGraph and displayed on the GUI Graph View. The SPAdes assembly graph contains 2186 nodes and 3061 edges, after the assembly shows 2 circular paths representing the chromosome and one plasmid.

Supplementary Figure 3 presents an example of the results before and after graph resolving process in the GUI. The result graph, after cleaning, would only report the significant connected components that represents the final contigs. Smaller fragments, even unfinished but with high remaining coverage, are also presented as potential candidates for further downstream analysis. Further annotation utility can be implemented in the future better monitoring the features of interests as in npScarf.
